SUPPLEMENTARY DISCUSSION

Phylogenetic relationships

We recover three well-differentiated clades plus three species with apparently no close relative (*L. syriaca*, *L. dezina* and *L. ossmar*). One of the strongly supported clades is formed by *L. punctifera* and *L. bellargus*, a grouping that corresponds very well to morphology. In fact *L. punctifera* and *L. bellargus* are so similar in their wing patterns that the taxon *punctifera*, first described by Oberthür in 1876 was initially considered a subspecies of *L. bellargus*. Much later, de Lesse (1959) assigned *punctifera* species status based on differences in chromosome number. These two taxa split ca. 0.74 Mya, possibly because of dispersal across the West Mediterranean (perhaps through the Gibraltar Strait), since *L. bellargus* is widespread in the Iberian Peninsula and across Europe into Western Asia, while *L. punctifera* is confined to the Southwestern Mediterranean shore (Morocco, N. Algeria and NW. Tunisia). The removal of the conflicting signal created by the mitochondrial sequence of *L. bellargus* JC96Q001 substantially increases the posterior probability of this clade (*pp* from 0.82 to 0.98). This specimen was collected in Germany, where *L. bellargus* flies syntopically and synchronically with *L. coridon*. Indeed, the introgressed mitochondrial haplotype has already been shown to be very widespread in Romania, where nine out of ten sequenced Romanian *L. bellargus* specimens carried the introgression (Dincă et al., 2011).

Another supported clade includes all Iberian taxa (*L. albicans*, *L. coelestissima*, and *L. hispana*) + *coridon* sensu stricto group (including the taxa *gennargenti*, *nufrellensis*, and *philippi*) (Figure 2A-2B). Two differentiated clades are recovered in the mitochondrial tree (Figure 1). One, which we will call the eastern clade, is well supported and comprises only *L. coridon*, mainly from central and eastern Europe. The

other, which we will call the western clade, is not well supported, and contains the remainder of the *L. coridon* samples from the Iberian Peninsula and Southern France, which cluster together with the other three Iberian taxa. The internal relationships for this group display a high degree of phylogenetic uncertainty. Notably, the four Iberian taxa and *L. coridon* are not recovered as monophyletic. Introgression is likely at play within this western clade, although JML could not differentiate it from the uncertainty created by incomplete lineage sorting. As shown in Figure 2C, the *L. coridon* specimens from the western clade were usually collected in sympatry or proximity to some of the other three Iberian taxa.

A macropopulation structure dividing *L. coridon* into an eastern and a western European form has been previously suggested (Schmitt and Seitz, 2001; Schmitt et al., 2002; Schmitt and Zimmermann, 2011). While our results generally agree with the proposed distribution of these two forms, remarkable additions to the known phylogeography of the species are worth discussing. First of all, a *L. coridon* specimen from Monte Pollino (Calabria, Southern Italy) displays a highly diverged haplotype with unresolved position in the tree, and it could represent a relict lineage that has survived in this rather isolated locality. Similarly, the Sardinian taxon *gennargenti*, while apparently related to the eastern clade, is also substantially diverged, which suggests that it has remained isolated for a substantial amount of time. Rather surprisingly, the geographically close taxon *nufrelensis* from Corsica belongs instead to the eastern clade, and its mitochondrial sequence is close to that of one French *L. coridon narbonensis* specimen studied, among others. Thus, *nufrelensis* is apparently the outcome of a more recent colonization of Corsica from the mainland, despite having some phenotypic

differentiation that could be either the result of a founder effect, drift or adaptation to insular conditions.

The other insular population studied is from the UK, which also belongs to the eastern clade and is almost identical to the French *L. coridon narbonensis* specimen. Thus, we can conclude that *L. coridon* may have colonized Great Britain quite recently from the mainland.

Our results show that the clear-cut division proposed for the two *L. coridon* forms, with a contact zone in north-eastern Germany, along the mountain ranges of the German–Czech border and throughout the eastern Alps (Schmitt and Zimmermann, 2012), is much more complex than originally proposed, at least for mitochondrial markers. Indeed, at least two specimens from the eastern clade were collected in surprisingly western locations: one was *L. coridon narbonensis* MAT99Q932 from Mende (Languedoc region, France). The other specimen is *L. coridon asturiensis* RV07C272 collected in the extreme north-western Iberian Peninsula (Figure 2C). Worth noting, this novel population, which represents the westernmost locality for *L. coridon*, occurs in an isolated small cape situated outside the area of influence of any other Iberian *Lysandra* species.

The two *L. coridon* clades may be the outcome of two different glacial refugia (the western clade in the Iberian Peninsula and the eastern clade in the Italian or Balkan Peninsulas, with postglacial dispersal creating the current distribution (Schmitt et al., 2002). However, we propose that isolation during the last glaciation has not generated most of the intraspecific divergence detected in *L. coridon*, but that the four taxa in the

Iberian refugium shared mitochondrial sequences in a high degree. The hypothesis of introgression between *L. albicans*, *L. coelestissima*, *L. hispana* and western *L. coridon* is further supported by the species tree treating separately the *L. coridon* eastern and western clades, which recovers them as paraphyletic lineages because the western clade is sister to the other three Iberian taxa (Figure 2D). While introgression within the Iberian Peninsula could not be unambiguously demonstrated by JML, this hypothesis is more likely than solely incomplete lineage sorting being the cause. Indeed, the presence of the eastern form in the extreme northwest Iberian Peninsula can hardly be explained by recent long-range dispersal. This isolated and ecologically unique population, located outside the area of influence of the other Iberian taxa and of other *L. coridon* populations (Figure 2C), shares a chromosome number with its geographical neighbours, and is most probably a relict of “pure” Iberian *L. coridon* that was not introgressed, which would mean that most of the western clade genetic differentiation is actually derived from events of introgression.

Within the *coridon* group, we consider the somewhat morphologically differentiated taxa *gennargenti* and *nufrellensis* as *L. coridon* subspecies because their genetic divergences fall within that of *L. coridon* sensu stricto. The taxon *gennargenti* is morphologically different from other forms of the *L. coridon* complex and due to the blue color of wing upperside in both males and females it was considered sometimes as a species distinct from *L. coridon* (Jutzeler et al., 2003). However, recent hybridization experiments (Schurian et al., 2011) demonstrated an absence of reproductive isolation between the taxa *gennargenti* and *nufrellensis*, concluding conspecificity of both taxa with *L. coridon*. No information is available on their chromosome numbers, and they are allopatric. The taxon *philippi*, which flies in Northern Greece, is genetically

identical to *L. coridon graeca* from Central Greece. Indeed, the taxon *philippi* was described as a separate species due an erroneous chromosome number count: Brown and Coutsis (1978) determined its chromosome number to be n=20-26, but no figures were provided. Later on, Coutsis et al. (2001) examined the karyotype of *philippi* again and found n=88-90, with one large chromosome. As its chromosome number does not differ from nearby *L. coridon*, its species status no longer seems warranted.

The generally parapatric, but sometimes locally sympatric, Iberian taxa require more complex assessment. Even if they frequently hybridize, they seem to present stable differences in chromosome number, and we tentatively consider *albicans*, *hispana* and *coelestissima* as three recent species.

Lastly, we recover the *corydonius* group as monophyletic. This includes four taxa from the Caucasus (*corydonius*, *arzanovi*, *melamarina* and *sheikh*) that are often considered subspecies of a single species, *corydonius* (Vodolazhsky and Stradomsky, 2008). Their divergence is minimal and they are estimated to have diverged ca. 0.25 Mya. They all seem to be allopatric, and differ in certain morphological characteristics and voltinism. The taxon *melamarina* is bivoltine, and differs from other representatives of the *coridon* subgroup by a very light, whitish color of the underside wing. The taxon *sheikh*, however, is monovoltine, and close to other representatives of the *coridon* subgroup, although displaying more bluish upperside wings in males and larger marginal black spots. The taxon *arzanovi* was described on the basis of putative chromosomal differences, as well as tiny differences in male genitalia (fine structure of gnathos) and male wing color (wing underside is grey whereas it is whitish in *melamarina* and brown in *corydonius* and *sheikh*).

However, since the chromosomal data we provide (n=84 for *L. melamarina*, *L. sheikh* and *L. corydonius*) cast doubt on previously reported chromosomal differences within this complex, we propose provisionally treating these taxa as conspecific until further evidence is obtained. Indeed, no predominant fixed barriers seem to exist between them, and the fact that they appear to be isolated, parapatric populations with some degree of phenotypic differentiation encourages us to treat them as subspecies *sensu* Braby et al. (2012).

The case of *L. ossmar*, a taxon that is usually considered to be closely related to the parapatric *L. corydonius* (Schurian, 1989; Hesselbarth et al., 1995), is especially interesting. While Schurian (1989, p. 158) conducted a morphological and ecological analysis that recovered *L. ossmar* as sister to the *L. corydonius* clade, in our dataset this is shown to be an effect produced by detected cases of mitochondrial introgression between these two taxa. Indeed, when removing the two potentially introgressed sequences, *L. ossmar* is recovered as an independent lineage with no close relative and unresolved position, similarly to the result for the middle-eastern taxa *L. dezina* and *L. syriaca*.

Table S4. Parsimony informative sites and number of positions per each loci for the *Lysandra* species.

Gene	Parsimony informative sites	Number of positions
CO	153	2164
CAD	2	745
Wg	15	403
ITS2	10	635
28S	3	821
H3	4	329
Rpl5	21	873

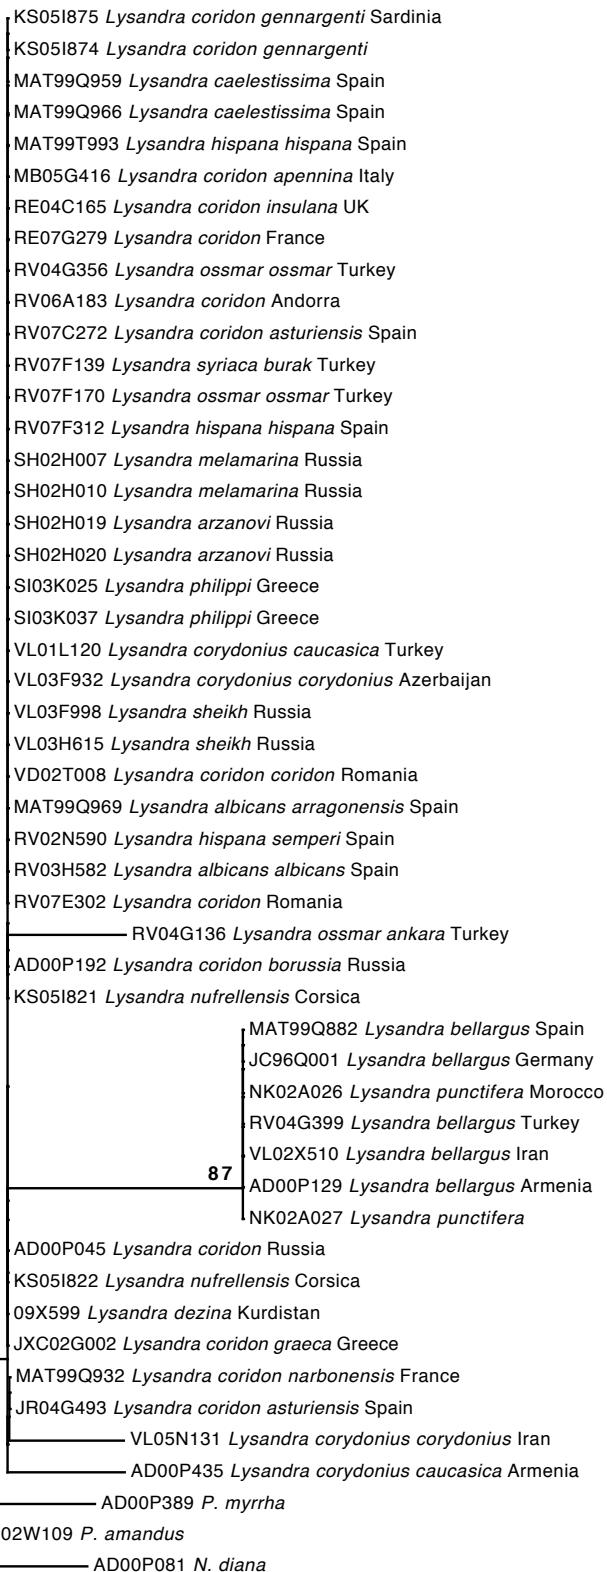

Table S5. Demographic history from *BEAST species tree inference. Values are extracted from Biopy consensus tree summaries. The X axis represents divergence time and Y axis represents relative population sizes width. Demographic values (dmv) for coalescence beginnings and ending points in branches are shown according to piecewise linear model used in *BEAST. Node ages are summarized using TreeAnnotator.

	dmv_b	dmv_e	dmv95_b	dmv95_e	Node age
